# 1 Introduction

Accelerating a particle beam in a plasma is an attractive concept because the plasma itself is capable of sustaining significantly higher accelerating fields than conventional RF structures. Conventional RF structures suffer electrical breakdowns at very high electric fields, and these breakdowns can over time damage the accelerator structures [2]. This puts an upper limit on the accelerating gradient of around 350 to 400 MV/m. The practical upper limit is however determined by the statistical probability of a breakdown and the acceptable number of breakdowns in a given period of time [3].

### Data Analysis

It has been very useful to develop a tool for effective analysis of the large amount of data produced by the Osiris and QuickPIC simulations used in this study. Most of the initial studies have been done using Osiris, and while the emittance studies have been mostly done using QuickPIC.

For the experiment itself a portion of the PhD project has been spent developing data acquisition tools and integrating these with the existing CERN data acquisition infrastructure.

As of the time of writing, the OsirisAnalysis framework is publicly available on GitHub [1].

#### B.1 Osiris Analysis Framework

The OsirisAnalysis framework is a modular and object oriented data analysis framework written in MATLAB. It was designed as a three layer tool to wrap a single data set of OSIRIS simulation data.

- **Layer 1:** Consists of the core datawrapper, OsirisData, which provides an interface through which raw data files as well as the simulation input file is parsed. It provides a uniform method for extracting data, and gives access to all the simulation parameters and conversion factors for converting Osiris' normalised units into SI units.
- **Layer 2:** The second layer consists of a set of classes that takes an OsirisData object as input, and returns standardised structs of data that can be scaled and converted to preferred units. They perform often needed tools and methods to parse data and extract more detailed information from the larger raw datasets.
- **Layer 3:** The third layer consists of a number of useful standardised plots and a GUI tool to quickly do a preliminary analysis of simulation data.

The philosophy behind this layering of the analysis tool is to allow the user the freedom to choose how many of these they will use. Only using the first layer will give the user access to all the simulation parameters as well as a method to extract data in a standardised manner and return a simple matrix of its content. Adding the second layer gives additional access to automatic unit conversion and other tools if needed. The third layer is entirely optional and simply provides a quick way to browse through the data.

### B.1.1 OsirisAnalysis Core Objects

The innermost layer consists of two classes `OsirisData` and `OsirisConfig`.

The `OsirisData` class wraps the simulation data folder and is the core interface through which data is extracted. The class also provides some simple methods for extracting information about the dataset like physical dimensions of the beam and the distribution of the plasma.

The `OsirisConfig` class is a wrapper for the input file itself, and contains a parser for this file which extracts all the relevant information for both analysis and provides lists of available diagnostics for the graphical user interface (GUI). All conversion factors to SI units are calculated on the fly when the input file is loaded. The `OsirisConfig` class is not intended to be called by the user, but is found as a child object of the `OsirisData` data object.

### B.1.2 OsirisAnalysis Data Types

The secondary layer of the `OsirisAnalysis` framework is a set of subclasses under a parent class named `OsirisType`. The subclasses will give access to specific types of data more or less directly related to the diagnostics types produced by the OSIRIS simulation code.

The classes provided are:

- **Density and Field:** These are classes that produce grid diagnostics data for the particle density data dumps or the field diagnostics data. They support all the different density diagnostics outputs of Osiris, and will in addition calculate the wakefields from the magnetic and electric fields given by  $W = F/q = E - v \times B$ .
- **Momentum:** The Momentum class consists of a set of methods that will calculate the evolution of the beams energy and momentum over several time dumps.
- **Phase:** The Phase class provides several tools for phase space diagnostics, including calculations of Twiss parameters.
- **UDist:** This class is similar to the Dnesity and Field classes, and provides methods to process velocity and thermal distribution data.
- **Species:** The Species class provides a few additional specialised tools for calculating energy deposition and gain into and from the plasma by the beams, and is also the class where particle tracking data is parsed.

In addition to these data parsing classes, there is also a `Variables` class that will translate Osiris diagnostics variables into readable forms and into strings usable for plot labels. There is also a `MathFunc` class that provides a math parser that emulates the one used by OSIRIS to parse mathematical functions from the input files. This class is mainly used to extract geometric information about beam density based on the function provided in the input file without the need to first run the code to provide raw particle data.

### B.1.3 OsirisAnalysis Graphical Interface and Plots

The final layer of the `OsirisAnalysis` framework is a set of very flexible plotting tools. Most of them have a long list of optional input argument. Most of these optional arguments are available through a graphical interface also written in MATLAB named `AnalysisGUI`.

## Abstract

We investigate beam loading of a plasma wake driven by a self-modulated proton beam using particle-in-cell simulations for phase III of the AWAKE project. We address the case of injection after the proton beam has already experienced self-modulation in a previous plasma. Optimal parameters for the injected electron bunch in terms of initial beam energy and beam charge density are investigated and evaluated in terms of witness bunch energy and energy spread. An approximate modulated proton beam is emulated in order to reduce computation time in these simulations.

## INTRODUCTION

The AWAKE experiment [1] is a proof-of-principle demonstration of acceleration of an electron bunch to the TeV energy range in a single plasma section, using a proton bunch driver [2].

Figure 1: Simplified set-up of AWAKE Phase III. A long proton bunch experiences the SMI in a short plasma cell. The electron bunch is injected before the second plasma cell.

The AWAKE experiment proposes using a proton driver at 400 GeV, delivered by the SPS. The experiment is currently under construction at CERN, scheduled to start in late 2016. The SPS proton bunch is too long to generate a sufficiently strong wakefield [3]. A usable drive bunch needs to be close to the plasma wavelength  $\lambda_p$  in length; however, producing a short enough proton bunch is technically difficult.

The plasma wavelength and frequency are given by

$$\lambda_p = \frac{2\pi c}{\omega_p}, \quad \omega_p = \sqrt{\frac{N_p e^2}{m_e \epsilon_0}}, \quad (1)$$

where  $N_p$  is the plasma electron density,  $e$  is the elementary charge,  $m_e$  is the electron mass and  $\epsilon_0$  is the vacuum permittivity.

A proton bunch with  $\sigma_{z,0} k_p \gg 1$ , where  $\sigma_{z,0}$  is the initial length of the bunch, will under certain conditions develop a self-modulation instability (SMI) when it travels through a plasma [4]. The proton bunch will then develop into a train of micro bunches with a period on the order of  $\lambda_p$ .

\* v.k.b.olsen@fys.uio.no

In phase I of the AWAKE experiment the SMI of the proton bunch will be studied. In phase II, the proton wake will be studied using a long, externally injected electron bunch that will sample all phases of the wake. In phase III, acceleration of a short bunch in the wake of an already self-modulated proton beam will be studied, as illustrated in Fig. 1. In this paper we study the beam quality of a short electron bunch accelerated by an SMI proton wake in preparation for phase III of AWAKE.

Figure 2: **Top:** An example showing the structure of the plasma electrons (grey) with a projection of the proton beam (red) and the electron bunch (blue) density on the bottom. The  $E_z$  (green) and  $E_r$  (yellow) fields have been overlaid on the plot. Shown is also a sample of electron (blue) and proton (red) macro particles. **Bottom:** An example of a pre-modulated proton drive beam at  $t = 0$  plotted in terms of charge density.

## SIMULATION SET-UP

All simulations in this paper have been performed using OSIRIS, a three-dimensional, relativistic, particle-in-cell code for modelling plasma based accelerators [5].

The parameter scans presented have all been run on a small scale test case with a shorter proton drive beam than AWAKE specifications. We simulate here only the second plasma stage in Fig. 1, assuming a pre-modulated proton beam profile with charge density function

$$\rho_{p^+}(\xi) = A \left[ \frac{1}{2\sqrt{2}} + \cos(k_p \xi - \mu_1) \right] e^{-r^2/2\sigma_r}, \quad (2)$$

where  $A$  is a charge scaling factor,  $\mu_1$  is the centre position of the first micro bunch,  $k_p = 2\pi\lambda_p^{-1}$  is the wave number, and  $\xi = z - ct$  is the coordinates in a frame moving at the speed of light.

The length of the beam is limited by a step function to 33 mm. Negative density values for the density profile is ignored by OSIRIS. This gives a beam of 26 micro bunches of protons, as seen in the bottom plot of Fig. 2. The beam has a total initial charge of 2.6 nC, with an initial peak current per micro bunch of 135 A. For the proton beam  $\sigma_r = 200 \mu\text{m} = 1.00 c/\omega_p$  in all simulations, where  $c/\omega_p$  is the plasma skin depth.

The electron witness bunch is injected between micro bunches 20 and 21 of the drive beam, at  $\xi \approx 12 \text{ mm}$ , see Fig. 2. The charge density of the electron bunch is given by

$$\rho_e(\xi) = Ae^{-(\xi-\mu)^2/2\sigma_z}e^{-r^2/2\sigma_r}. \quad (3)$$

For the electron bunch  $\sigma_r = 105 \mu\text{m} = 0.52 c/\omega_p$ , and  $\sigma_z = 40 \mu\text{m} = 0.2 c/\omega_p$  in the cases with a short electron bunch. The plasma density at the beginning of the plasma section for all these simulations is  $N_p = 7 \times 10^{14} \text{ cm}^{-3}$ .

### BEAM INJECTION

While the peak-to-peak distance between micro bunches of the self-modulated proton beam corresponds closely to the plasma wavelength  $\lambda_p$ , it is not constant along the length of the beam [6]. A brief study of the SMI of both full scale and small scale proton beams, using Fourier transform and Wavelet analysis, revealed that the fundamental frequency was slightly lower than one  $k_p$ .

Figure 3: **Top:** The Fourier transform of the proton beam after 10 m of plasma for a self- and pre-modulated beam. The green line indicates  $k_p = 2\pi/\lambda_p$ . **Bottom:** Typical drift of a proton and electron macro particle through the plasma in respect to  $c$ .

To minimise further SMI development with a pre-modulated beam, the micro bunch distance was reduced

to  $0.9939 k_p$ , which produced a very good fit to the actual SMI for our test case, see Fig. 3.

An electron bunch of low MeV range initial energy will, due to its low gamma factor compared to the 400 GeV proton beam, slip backwards. In order to minimise this effect we set the initial energy of the electron bunch to 30 MeV, a little higher than AWAKE parameters. Typical slip for the beams through 10 m of plasma is illustrated in Fig. 3.

Staying in phase with the drive beam is essential to optimise energy transfer. Establishing an optimal injection point of the electron bunch was achieved by using bunches with length in the order of one  $\lambda_p$ , and tracking a selection of the electrons with optimal energy gain back to  $z = 0$ .

### BEAM LOADING AND ENERGY SPREAD

In a plasma wakefield accelerator, the witness bunch should be accelerated at high efficiency while preserving a low energy spread. Beam loading in the linear regime can be calculated by the linear addition of fields. Only very narrow electron bunches, with  $\sigma_r \ll c/\omega_p$ , can maintain low energy spread and emittance [7, 8].

Figure 4: Comparison between the  $E_z$  field at 1 m (light green) and 10 m (dark green) of plasma for four different electron bunch currents. The fields are averages over a region  $10 - 25 \mu\text{m}$  from the axis. A dimensionless plot of the charge density of the electron bunch is added in blue.

In the non-linear blowout regime, the plasma electrons are blown out by the drive beam, leaving behind a uniform region of plasma ions. The ions pull the electrons back towards the axis, forming a bubble with length on the order of the plasma wavelength [8, 9]. In this regime, the charge and current profile required to optimally load the wake can be estimated analytically. Optimal loading results in a flat  $E_z$  field across the bunch with high wake to beam energy transfer efficiency. There is a trade-off between the number of particles that can be accelerated and the accelerating gradient, as discussed in detail by Tzoufras et. al [10].

### 3: Alternative Particle Sources and Acceleration Techniques

#### A22 - Plasma Wakefield Acceleration

The beam-plasma interaction studied in this paper has similarities with the above blowout regime, but the train of micro bunches produces a more complex wakefield [4]. We have studied the beam loading through simulations. Based on beam loading in the blowout regime, we use as starting point for the studies a witness bunch with the same peak current as the initial peak current of one proton micro bunch, 135 A. We then performed a scan with logarithmic steps of current from 13.46 A to 13.46 kA. A selection of these are shown in Fig. 4, significant loading of the  $E_z$  field does occur when the witness bunch has significantly higher current than the proton beam. An approximate flattening of the field is observed when the witness bunch current is about 3 times higher than the initial micro bunch current, as shown in Fig. 4c. For higher witness bunch currents, we observe that the field from the witness bunch itself starts to dominate the wake it experiences, as expected. The trailing part of the electron bunch is therefore decelerated, as shown for example in Fig. 4d.

We notice that constant loading as the drive and witness bunch propagate in the plasma is not possible, as protons keep being ejected radially throughout the plasma, eating up the micro bunches from the front. This leads to the energy gain levelling off after approximately 4 m of plasma, turning into energy loss as the dephasing between the electron bunch and the  $E_z$  fields becomes too large. The phase difference of  $E_z$  at 1 m and 10 m is shown in Fig. 4. The mean energy gain (816.2 MeV) and relative energy spread (12%) of the electron bunch, as it travels through the plasma, is visible in blue in Fig. 5, showing a case with peak electron current of 425.5 A. The peak current of a micro bunch after 10 m of plasma, within one skin depth of the axis, is only 45 A.

Figure 5: **Top:** Energy gain through 10 m of plasma for a short electron witness bunch with  $\sigma_z = 40 \mu\text{m}$  and  $I = 425.5 \text{ A}$ , for the case of no plasma gradient and 3.5% plasma gradient. **Bottom:**  $\xi - p_z$  phase plot for both simulations at the end of the plasma.

## PLASMA GRADIENT

Due to the backwards drift of the  $E_z$  field, the electron bunch falls out of optimal phase after a few metres of plasma. It is possible to stabilise the accelerating bucket by gradually increasing the plasma density. We performed a scan of plasma gradients ranging from 0% to 10% along 10 m of plasma, with a square bunch of length  $\lambda_p$ . We found that a gradient of  $0.2 - 0.3 \times 10^{14} \text{ cm}^{-3}$  (3 – 4%) per metre plasma for our initial density of  $7 \times 10^{14} \text{ cm}^{-3}$ , produced the highest energy gain for the electrons with optimal phase. By tracking some of these electrons back to their injection point, we could move the centre of the short bunch and do a new simulation comparing no gradient to a 3.5% gradient. The best result was for a gradient with a density at 10 m of  $7.245 \times 10^{14} \text{ cm}^{-3}$  (3.5%), see Fig. 5 and Table 1.

Table 1: Electron Bunch Energy After 10 m of Plasma

Energy	No Gradient	3.5% Gradient
Mean	846.20 MeV	1618.77 MeV
RMS	101.23 MeV	54.93 MeV
RMS/Mean	11.96 %	3.39 %

## CONCLUSION

We have studied beam loading of a SMI proton wake. A scan of electron witness bunch charges over three orders of magnitude revealed that a witness bunch peak current of about a factor 3 higher than the initial peak current of one proton micro bunch was optimal for flattening the wakefield. It is important to note that protons keep getting ejected radially, resulting in a loss of proton charge close to the axis, as the beam travels through the plasma. This decreases the current of a micro bunch by a factor of  $\sim 3$  in the no gradient case.

The electron bunch does not stay in optimal phase for very long as the  $E_z$  field starts to drift significantly after 2 – 4 m of plasma. In most simulations the bunch ends up around the zero point of the  $E_z$  field, and the energy gradient flattens, and in some cases turns negative. For our optimal case of phase and charge, this effect could to a large degree be counteracted by a 3.5% gradient of the plasma, which forces a positive phase shift of the  $E_z$  field, keeping the electron bunch synchronous with the accelerating phase of the wake.

## ACKNOWLEDGEMENT

The authors would like to acknowledge the OSIRIS Consortium, consisting of UCLA and IST (Lisbon, Portugal) for the use of OSIRIS, for providing access to the OSIRIS framework.

## Abstract

Using parameters from the AWAKE project and particle-in-cell simulations we investigate beam loading of a plasma wake driven by a self-modulated proton beam. Addressing the case of injection of an electron witness bunch after the drive beam has already experienced self-modulation in a previous plasma, we optimise witness bunch parameters of size, charge and injection phase to maximise energy gain and minimise relative energy spread and emittance of the accelerated bunch.

## INTRODUCTION

The AWAKE experiment at CERN proposes to use a proton beam to drive a plasma wakefield accelerator with a gradient on the order of 1 GeV/m to accelerate an electron witness beam [1, 2].

In this paper we present two simulation configurations with a modified proton drive beam based on the baseline parameters for the AWAKE experiment. The drive beam is delivered from the SPS accelerator at CERN at an energy of 400 GeV/c, a bunch length  $\sigma_z = 12$  cm, and  $\sigma_{x,y} = 200 \mu\text{m}$ . [3].

The baseline plasma electron density  $n_{pe}$  for AWAKE is  $7 \times 10^{14} \text{ cm}^{-3}$ . The corresponding plasma wavelength  $\lambda_{pe} = 2\pi c/\omega_{pe} = 1.26$  mm, where  $c/\omega_{pe} = 200 \mu\text{m}$  is the plasma skin depth, and  $\omega_{pe}$  is the plasma frequency given as  $[n_{pe}e^2/m_e\epsilon_0]^{1/2}$ .

In order to generate a suitable wakefield, the drive beam must be shorter than  $\lambda_{pe}$ . This is not achievable for the SPS proton beam. In order to use such a beam to drive a wakefield we exploit the self-modulation instability (SMI) that can occurs when the beam travels through a plasma and  $\sigma_z \gg \lambda_{pe}$ . The SMI modulates the beam at a period of  $\approx \lambda_{pe}$  [4], allowing us to inject the witness beam in an optimal bucket between two such proton micro bunches.

## BEAM LOADING

A particle beam at high energy travelling through a plasma will excite a plasma wave in its wake, and the plasma can sustain a very high accelerating gradient [5]. It is possible to accelerate a secondary beam by extracting energy from this wakefield, thus transferring energy from a drive beam to a trailing witness beam. Such an accelerator design was first proposed by Chen in 1985 [6]. However, there are some challenges in this transfer of energy from drive to witness beam.

\* v.k.b.olsen@fys.uio.no

Figure 1: Energy gain and spread for a series of witness beams after  $\approx 1.1$  m of plasma. The initial momentum of the witness beam is 217.8 MeV/c. Mean momentum and RMS spread is calculated for all macro particles in the PIC simulation.

One such challenge stems from the witness beam generating its own field, modifying the  $E_z$ -field behind it such that the particles in the tail will be accelerated less than those in the front. This causes an increase in energy spread in the beam [7]. This effect can in theory be corrected for by shaping the witness beam. An optimally shaped and positioned beam, such as a triangular beam, can flatten the wakefield such that change in energy spread is effectively zero [8]. However, this requires beam shapes that are difficult to produce experimentally.

## BEAM LOADING OF SMI WAKEFIELDS

For AWAKE, most of the SMI evolves during the first stage of  $z < 4$  m [2]. This evolution results in a phase change of the wakefields that causes the optimal point for acceleration to drift backwards relative to the witness beam [9, 10].

In our current study we have restricted ourselves to Gaussian witness beams, and seek to demonstrate through simulations how small energy spread can still be achieved by optimally loading the field. The first set of simulations presented uses a subset of 26 micro bunches resulting from the self-modulation that occurs in the previous plasma stage. The pre-modulated beam does undergo further evolution as the envelope function does not fully match the SMI beam, but we only look at the first  $\leq 3$  m of this stage, before the phase change starts to dominate [11]. All simulations have been done using OSIRIS 3.0 [12].

A second set of proposed simulations for the second plasma stage will use a single drive beam scaled to produce an accelerating field of 500 MV/m, but with its transverse evolution inhibited in order to study the loading of the field produced by the witness beam alone. The drive beam is short,  $\sigma_z = 40 \mu\text{m} \ll \lambda_{pe}$ , which is well below the SMI limit.

## MULTI DRIVE BUNCH SIMULATIONS

In the multiple drive bunch simulations we assume self-modulation has occurred in a previous stage, and approximate the resulting proton beam in the second stage where acceleration of the witness beam occurs. In this first series of studies we have used a short series of 26 proton bunches with a clipped cosine envelope. This setup is about 10 times shorter than full scale AWAKE simulations, allowing us to run more detailed parameter scans. The setup is described in more detail in our IPAC'15 proceedings, where we looked at beam loading as well as the evolution of the proton beam in a 10 m plasma section [11].

Figure 2: Loading of the field after  $\approx 1.1$  m of plasma for a 400 A/60  $\mu\text{m}$  electron beam. A sample of electrons (blue) and protons (red) are plotted with their respective projection at the bottom. The total charge within the region of the plot is given as the first two lines of the legend. The longitudinal e-field  $E_z$  is shown in green. The transverse wakefield  $W_r = E_r - v_z B_\theta$  is shown in orange, where  $v_z = c$  is the moving frame of the simulation. The fields are averages over 15  $\mu\text{m}$  near the axis.

The quality and energy of the accelerated witness beam depends on both its position in relation to the field as well as how uniform the field is in the region where the beam is located. We have matched the initial  $\gamma$  of both witness and drive beam in order to avoid initial slipping of the witness beam with relation to the wakefield. The accelerating phase of the field is in the order of  $\lambda_{pe}/4 \approx 300 \mu\text{m}$  in length, which puts a constraint on the longitudinal size of the witness beam. The transverse size  $\sigma_r = 100 \mu\text{m}$ , however we observe in simulations that the beam shrinks by a factor of 4 – 6 as it enters the plasma section. This again results in a sharp

increase in charge density. A scan of different beam sizes and initial beam current and their corresponding energy gain and spread is shown in Fig. 1.

The best result in terms of total energy spread is for the 40  $\mu\text{m}$  beam of an initial current of 200 A, and for the 60  $\mu\text{m}$  beam of an initial current of 400 A. The former beam carries 67 pC and the latter beam 200 pC. As we want to load the field as close to its maximum as possible, this comes at a cost as the tail of the beam will extend beyond the optimal point into the defocusing region of the wakefields. Fig. 2 shows a snapshot of the 60  $\mu\text{m}$ /400 A simulation from Fig. 1. The longitudinal field is nearly flat as a result of the loading.

Figure 3: Electron beam momentum spread after  $\approx 1.1$  m of plasma for the 400 A/60  $\mu\text{m}$  beam. 75 % of the beam charge is accelerated to more than 440 MeV/c, the vertical grey line. The fit is applied to the data above this line,  $R^2 = 0.755$ .

A closer look at the energy spread in Fig. 3 reveals that  $\approx 75$  % of the beam is accelerated in this region, with a long tail in energy. This case is not only optimal in terms of beam loading, but also in energy spread of the bulk of the beam of 150 pC. For that part of the beam in front of the grey line we get a relative energy spread  $\sigma_{P_z}/[P_z - P_{z,0}] = 1.5$  %. The tail of the beam in terms of energy is lagging behind as it is experiencing defocusing and being pushed outwards and eventually lost from the plasma channel. This loss of beam in the tail can be counteracted by shaping the beam, and making the backwards half  $\sigma_z = 20 \mu\text{m}$  and keeping the forward half at  $\sigma_z = 60 \mu\text{m}$ . In simulations this has reduced this loss to 4 – 5 %. However, such shaping of the beam is technically difficult.

Figure 4: The 400 A/60  $\mu\text{m}$  electron beam as it travels through plasma. The left plot shows the mean energy of the beam with the RMS energy spread as a shaded bar. The right plot shows the RMS radius in blue, and the percentage of macro particles the are within 20  $\mu\text{m}$  of the axis in red.

The relative energy spread of 1.5 % is still undesired. The witness beam in these simulations is initiated with no energy spread in the longitudinal direction. Fig. 4 shows that for our best case the energy spread we see mainly develops in the first 20 cm of plasma. As the right plot illustrates, the transverse RMS size of the beam shrinks by a factor of 5 over the first metres of plasma, but already after a few centimetres about 80 % of the charge is found near the axis. It is this more compact beam that optimally loads the field, and for the first 20 cm the field is under-loaded, probably causing the increase in energy spread. This, however, needs to be studied further.

## SINGLE DRIVE BUNCH SIMULATIONS

In order to study the loading of the accelerating e-field in more detail, a second set of simulations have been set up where we have a single proton drive bunch driving a wakefield on the order of 500 MV/m, which is the magnitude of the field we expect to see in the second plasma stage of AWAKE Run 2, based on simulations [13, 14].

This series of simulations is set up in such a way that the accelerating field is as static as possible in order to eliminate other factors than the beam loading by the witness bunch. To achieve this, the proton bunch is prevented from evolving transversely by setting the proton mass to a much higher value than its real value. The gamma of the drive and witness bunches are again matched to prevent dephasing.

Figure 5: Loading of the field after  $\approx 28$  cm of plasma for a 500 A/60  $\mu\text{m}$  electron beam. As in Fig. 2 a sample of electrons (blue) and protons (red) are plotted with their respective projections, and the  $E_z$  and  $W_r$  wakefields are shown.

This provides a much cleaner environment to study the effects of beam loading from the electron beam alone without any evolution caused by the proton beam. Fig. 5 shows an example of this setup. It reproduces the transverse wakefields we saw in our 26 bunch simulations. We also see a shrinking of the witness beam in the first few centimetres, which, together with emittance evolution, is the focus of this next stage of on-going simulation studies.

## CONCLUSION AND CONTINUATION

There are a number of challenges with accelerating an electron beam by a self-modulated proton beam in plasma. Not only does the continued evolution of the proton beam affect the wakefield and thus the acceleration of the witness beam, but the evolution of the witness beam itself affects the wakefields, causing among other things, energy spread. However, by tuning the charge density of the beam, this loading of the field can be used to prevent continuing growth in energy spread provided the phase of the wakefield does not evolve too much.

This is an on-going study, and we are currently looking into the cause of the growth of energy spread. It is worth noting that we have so far run these simulations with an unmatched witness beam. We do see emittance growth in this same region where energy spread increases, but further studies are needed to properly understand the numerical contribution to both these effects.

## ACKNOWLEDGEMENTS

The authors would like to acknowledge the OSIRIS Consortium, consisting of UCLA and IST (Lisbon, Portugal), for providing access to the OSIRIS framework.

The numerical simulations have been possible through access to the Abel supercomputer maintained by UNINETT Sigma2 AS, and financed by the Research Council of Norway, the University of Bergen, the University of Oslo, the University of Tromsø and the Norwegian University of Science and Technology. Project code: nn9303k.

# Data Acquisition and Controls Integration of the AWAKE Experiment at CERN

**Abstract:** The AWAKE experiment has been successfully installed in the CNGS facility at CERN, and is currently in its first stage of operation. The experiment seeks to demonstrate self-modulation of an SPS proton beam in a rubidium plasma, driving a wakefield of several gigavolt per meter. We describe the data acquisition and controls system of the AWAKE experiment, its integration into the CERN controls system and new control developments specifically required for the AWAKE experiment.
